Introduction

Ewing sarcoma is a malignant bone and soft-tissue tumor primarily affecting children and young adults. Despite intensive chemotherapy, surgery, and radiotherapy approximately 50% of patients ultimately succumb to the disease. Ewing sarcoma is characterized by chromosomal translocations that fuse a member of the TET family to one of a subset of ETS transcription factors (1, 2). Eighty to 85% of Ewing Sarcoma tumors contain t(11;22)(q24;q12), generating an in-frame fusion of EWSR1 to FLI1 (2). The resulting chimeric EWS–FLI1 protein is a potent transcriptional modulator that regulates multiple genes implicated in malignant transformation (3, 4).

Several lines of evidence support a role for the insulin-like growth factor (IGF) pathway in the development of Ewing sarcoma. EWS–FLI1 regulates IGFI in Ewing sarcoma cell lines and is induced by EWS–FLI1 in mesenchymal stem cells (5–7). IGFI and its receptor (IGF1R) are expressed in tumors, and IGFI expression in cell lines leads to autocrine activation (8, 9). IGFI signaling is necessary for the survival and proliferation of Ewing sarcoma cells (10, 11), transformation of murine fibroblasts by EWS–FLI1 (12), as well as for normal bone development (13). The promising results of preclinical trials targeting the IGF pathway in Ewing Sarcoma have made it an attractive therapeutic target (14–17). However, studies of IGFI and IGF1R inhibitors in early-phase clinical trials have shown a limited response rate (18–20). A biomarker predictive of individuals who may respond to IGFI-mediated treatment remains to be identified (21, 22).

IGFI bound to IGF1R initiates a signaling cascade through the PI3K pathway, resulting in phosphorylation of downstream targets, including AKT. Phosphorylation of AKT at serine-473 (S473) and threonine-308 (T308)

Abstract

Recent evidence implicates the insulin-like growth factor (IGF) pathway in development of Ewing sarcoma, a highly malignant bone and soft-tissue tumor that primarily affects children and young adults. Despite promising results from preclinical studies of therapies that target this pathway, early-phase clinical trials have shown that a significant fraction of patients do not benefit, suggesting that cellular factors determine tumor sensitivity. Using FAIRE-seq, a chromosomal deletion of the PTEN locus in a Ewing sarcoma cell line was identified. In primary tumors, PTEN deficiency was observed in a large subset of cases, although not mediated by large chromosomal deletions. PTEN loss resulted in hyperactivation of the AKT signaling pathway. PTEN rescue led to decreased proliferation, inhibition of colony formation, and increased apoptosis. Strikingly, PTEN loss decreased sensitivity to IGFI1R inhibitors but increased responsiveness to temsirolimus, a potent mTOR inhibitor, as marked by induction of autophagy. These results suggest that PTEN is lost in a significant fraction of primary tumors, and this deficiency may have therapeutic consequences by concurrently attenuating responsiveness to IGFI1R inhibition while increasing activity of mTOR inhibitors. The identification of PTEN status in the tumors of patients with recurrent disease could help guide the selection of therapies.

Implications: PTEN status in Ewing sarcoma affects cellular responses to IGFI and mTOR-directed therapy, thus justifying its consideration as a biomarker in future clinical trials. Mol Cancer Res; 12(11); 1610–20. ©2014 AACR.
promotes cell-cycle progression, cell survival, migration, and metabolism through differential interactions with multiple substrates, including mTOR (23, 24). Signaling through the PI3K pathway is attenuated by PTEN through dephosphorylation of PIP3 (25). The loss of PTEN results in increased accumulation of PIP3 and AKT activation, which has been associated with poor clinical outcomes (26–28). The loss or mutation of PTEN has been demonstrated in a range of cancers (26–30); however, the function of PTEN in Ewing sarcoma has yet to be investigated.

Here, we describe PTEN loss in Ewing sarcoma and its consequences on IGF and mTOR signaling, as well as on biochemical responses to small-molecule inhibitors. PTEN deficiency augments PI3K signaling to AKT while diminishing cellular responsiveness to IGF inhibition. Interestingly, PTEN loss enhances sensitivity to autophagy induced by mTOR inhibition. Together, these data suggest how PTEN loss may influence the response to biologic therapies in Ewing sarcoma.

Materials and Methods

FISH

The RP11-383D9 (D9) and RP11-846G17 (G17) Bacterial Artificial Chromosomes (BAC) were obtained from the Children’s Hospital Oakland Research Institute. Bacterial cultures of both BACs were grown in Luria Broth with 25 μg/mL chloramphenicol and DNA extracted using Qia-gen Plasmid Midi Kit with slight modifications (10 mL of Buffer P1, P2, and P3 and DNA was eluted in 1 mL of PBS. Ten milliliters of KCl at 37°C was mixed and placed in a 37°C water bath for 12 hours, after which media were changed and the cells split for proliferation and soft-agar assays. Cells were stained with Trypan blue and counted using a hemocytometer to assay proliferation. For soft agar, 0.6% agar was used as the base layer and 0.5% agar as the top layer. The plates were counted manually using ImageJ (NIH, Bethesda, MD). Apoptosis was assessed using the Annexin V–Cy3 Apoptosis Detection Kit (Sigma-Aldrich) according to the manufacturer’s protocol. Flow cytometry was performed using the CyAn ADP (Beckman-Coulter). For assessment of autophagy, three days after lentiviral transduction, A673 and EWS502 cells were split 1:3 and treated with 20 μmol/L chloroquine for 3 hours or chloroquine followed by 10 ng/mL temsirolimus (LC Laboratories) for 20 hours. Cells were lysed in 3-[(Cholamidopropyl)dimethylammonio]-1-propanesulfonate buffer (CHAPS) and extracts were separated by SDS-PAGE.

IGFI inhibition

Cells were treated with NVP-AEW541 (Cayman Chemical) and OSI-906 (ChemieTek) at the indicated concentrations. Before treatment with IGFI, cells were kept in serum-free media for two hours in combination with the IGFI inhibitor. Cells were then treated with IGFI (Cell Signaling Technology) for 15 minutes and lysed in radioimmunoprecipitation assay buffer (25 mmol/L Tris-HCl pH 7.6, 150 mmol/L NaCl, 1% NP-40, 0.1% SDS) supplemented with 200 mmol/L NaVO4 and 50 mmol/L NaF. Cell extracts were separated by SDS-PAGE and blotted with anti-phospho AKT and imaged (LiCor). For assessment of cell viability, EWS502 cells were transduced with lentiviral pLL5.0-PTEN or pLL5.0 as a vector control. Twenty-four hours after infection, the cells were treated with NVP-AEW541 in complete media. Viability was assayed 72 hours after NVP-AEW541 treatment using WST-1 (Roche).
Tissue microarray and cell line array construction

Pellets from the Ewing sarcoma cell lines were fixed in 10% buffered formalin (SF98-4, Fisher Scientific) for 16 to 24 hours, washed twice in 70% ethanol, clotted in 2% low-melting agarose (Fisher), and then embedded in paraffin wax. Blocks were sectioned and stained with hematoxylin and eosin (H&E, Hematoxylin 7211, Eosin 7111; Richard-Allan). Three 1 mm cores were removed and embedded into recipient cell line array (CLA) block. For TMA construction, Ewing sarcoma cases (n = 25) and controls (breast carcinoma, and PTEN-deleted sarcoma) were selected from The University of North Carolina Surgical Pathology and St. Jude Children’s Research Hospital archives under an Institutional review board-approved protocol. H&E-stained slides were rereviewed and representative areas of tumor were marked for coring. TMA blocks, containing triplicate 0.6 mm cores per case, were constructed. TMA and CLA blocks were cut into 4- and 5-μm sections, respectively, and placed on positively charged glass slides.

Immunohistochemistry and immunofluorescence

TMA and CLA slides were stained with CD99 and PTEN antibodies (Bond fully automated slide staining system; Leica Microsystems). Slides were deparaffinized (Bond, AR9222) and hydrated in wash solution (Bond, AR9590). Epitope retrieval (pH 9.0, AR9640, Bond) was performed followed by a peroxide blocking step (Bond DS9800). CD99 and PTEN (1:400) antibodies were incubated for 15 and 30 minutes, respectively; then, secondary antibody was applied (polymer, Bond DS9800). Chromogenic detection with 3,3′-diaminobenzidine (DAB) and hematoxylin was performed (Polymer Refine Detection, DS9800, Bond). Stained slides were dehydrated and mounted. For fluorescent detection, the TSA-Cy5 reagent (PerkinElmer), Hoechst 33258 (Invitrogen), and ProLong Gold antifade reagent (Molecular Probes) were used.

Imaging and digital image analysis

Immunohistochemically stained TMA sections were digitally imaged (Aperio ScanScope XT, Aperio Technologies). High-resolution DAPI and Cy5 IF images were obtained (Aperio ScanScope FL). For digital images from IHC slides, Aperio Cytoplasmic algorithm was used to determine the percentage and intensity of cells positive for PTEN or CD99. A PTEN-deleted tumor control was used to set the negative/low positive intensity threshold for the PTEN-stained TMA slide. IF signal was quantified (Definiens Tissue Studio, version 3.6).

Results

A subset of Ewing sarcomas lack PTEN

We recently reported widespread alterations in chromatin structure and histone modifications in Ewing sarcoma cells using high-throughput sequencing (5). Although the experiments performed were intended to detect nucleosome-depleted regions of chromatin, background signal from Formaldehyde Assisted Isolation of Regulatory Elements (FAIRE-seq) typically covers the remainder of the genome mappable by short sequencing read and thus offers a genome-wide sampling of DNA content. Unexpectedly, we observed an approximately 1 Mb region on chromosome 10 that demonstrated a nearly complete loss of FAIRE-seq signal, which we hypothesized to indicate homozygous deletion (Fig. 1A). The potential deletion encompassed several genes, including the terminal exons of PTEN (Fig. 1A).

As deletion of PTEN had yet to be detected in Ewing sarcoma using high-throughput sequencing approaches, we verified this deletion by FISH using two probes that overlap the PTEN locus, as well as a control centromeric probe. One probe (G17) is fully contained within the deleted region, whereas half of the second probe (D9) was predicted to hybridize outside the deletion (Fig. 1A). Probes were hybridized to seven Ewing sarcoma cell lines (EWS502, EWS894, A673, MHH-ES-1, SK-ES, RD-ES-1, SK-N-MC) and one control cell line (HUVEC). The absence of signal from the G17 probe in EWS502 cells confirmed a homozygous deletion at this region (Fig. 1B). Signal from the D9 probe was detected which likely results from hybridization to the retained region centromeric to the deletion. Signal was observed for both probes in the other Ewing sarcoma and control cell lines. However, EWS894 and SK-N-MC cells exhibited PTEN/centromeric probe ratios not equal to one suggesting other cytogenetic aberrations involving the long arm or centromere of chromosome 10 (Fig. 1B and C). EWS894 had two copies of the PTEN locus but three copies of the centromeric probe, whereas one copy of the PTEN locus and two copies of the centromeric probe were detected in SK-N-MC. The PTEN/centromeric probe ratio was equivalent for the remaining cell lines; MHH-ES-1 and RD-ES exhibited triploidy of chromosome 10 (Supplementary Fig. S1). Consistent with PTEN chromosomal loss, PTEN protein was absent in EWS502, whereas other Ewing sarcoma cell lines showed variable levels (Fig. 1D).

To address whether PTEN was similarly lost in primary Ewing sarcoma tumor, we generated a TMA consisting of 25 tumors diagnosed as Ewing Sarcoma during clinical evaluation. The samples were rereviewed before microarray generation, and tumor-specific regions were selected for core preparation. Each tumor was represented in triplicate at random positions on the array. Microarray sections were hybridized to both FISH probes. For the 20 tumors from which FISH signal was interpretable, homozygous loss was not observed; however, copy number varied across tumors (Supplementary Fig. S2). As PTEN expression can be affected by mechanisms other than deletion, we analyzed PTEN protein levels by immunofluorescence and immunohistochemistry. A Ewing sarcoma cell line array was generated to validate antibody-mediated detection of PTEN. PTEN detection by IHC and IF on the cell line array quantitatively matched detection by Western blotting (R² = 0.74, Supplementary Fig. S3). Because of the diverse age of the samples that contributed to the primary tumor array and the evolving criteria for Ewing sarcoma diagnosis, we performed IHC and IF for CD99 as confirmation of diagnosis and as a quality control. IHC and IF for CD99 as
well as PTEN were highly concordant (Supplementary Fig. S4). After eliminating CD99-negative tumors and those with poor staining 15 tumors remained. A wide range of PTEN expression was detected by IF among the Ewing sarcoma samples. Three tumors demonstrated significantly reduced signal when compared with a PTEN-expressing control breast carcinoma sample and a PTEN-deficient undifferentiated sarcoma (Fig. 2A). Histologic examination suggested that nontumor cells confounded accurate PTEN quantification. We attempted IF for CD99 to specifically identify tumor cells, but due to technical constraints cost-saving of PTEN and CD99 was not possible. However, using CD99 IHC in adjacent sections, we confirmed the IF results. We observed that for one additional tumor (tumor 2, Fig. 2A and B), 55% of the cells did not demonstrate PTEN signal (Supplementary Fig. S5). Remaining PTEN expression in this sample may be related to CD99-negative nontumor cells or tumor heterogeneity (Fig. 2B). These data suggest that PTEN expression is reduced in approximately 25% (4/15) of Ewing sarcomas, and that the loss of PTEN is primarily through mechanisms other than large genomic losses. This observation is consistent with other tumors in which PTEN expression is lost due to gene silencing or focal deletions (32–35).

**PTEN loss in Ewing sarcoma augments AKT signaling**

To determine the effect of PTEN loss on AKT signaling across Ewing sarcoma cell lines, we examined phosphorylation at S473 and T308. Phosphorylation of these sites is indicative of AKT activation (23, 24). Among the cell lines tested, EWS502 had the highest level of pAKT (Fig. 3A). Low levels of S473 phosphorylation was also observed in EWS894, SK-ES, and RD-ES-1 cells. T308 phosphorylation was limited to EWS502. PDK1-associated phosphorylation of T308 is associated with full AKT activation (36, 37) and was only observed in the absence of PTEN,
suggesting that AKT activation is augmented by PTEN loss. We then ectopically expressed PTEN in EWS502 cells to test the association between PTEN levels and activated AKT. Increasing PTEN was associated with a progressive decrease in pAKT at S473 and T308 (Fig. 3B), suggesting that AKT activation in EWS502 is due in part to PTEN deficiency. To test whether PTEN loss altered IGFI sensitivity, we examined dose-dependent stimulation by IGFI under serum-free conditions. AKT demonstrated baseline phosphorylation in all Ewing sarcoma cell lines. IGFI stimulation resulted in further AKT activation. However, there was no difference in IGFI IC50 (Supplementary Fig. S6). These data indicate that PTEN levels influence AKT activation but do not result in enhanced sensitivity to IGFI.

The cellular effects of PTEN loss in Ewing sarcoma were examined by testing the effect of PTEN on cellular proliferation and anchorage-independent growth. PTEN was transduced into EWS502 cells and expression was confirmed by immunoblotting. PTEN expression resulted in significantly decreased cellular proliferation (Fig. 3C). To address whether the reduction in cell proliferation following PTEN expression could be attributed to increased apoptosis, we assayed Annexin V reactivity by flow cytometry and observed a significant increase relative to control cells (Fig. 3D). We also observed a similar increase in cleaved PARP (Supplementary Fig. S7). Anchorage-independent growth as assayed by colony formation in soft agar was also greatly diminished (Fig. 3E). Taken together, these data demonstrate that PTEN loss enhances cellular properties associated with transformation in Ewing sarcoma cells.

**PTEN loss decreases sensitivity to IGFI inhibition**

As clinical trials of IGFI-targeted inhibitors have demonstrated robust but limited patient responses, we asked whether PTEN loss might mitigate the effect of these compounds in Ewing sarcoma cells. Ewing sarcoma cells were treated with two IGF1R inhibitors, NVP-AEW541 (38) and OSI-906 (39). NVP-AEW541 has been tested for Ewing sarcoma, whereas OSI-906 is an investigational agent for a variety of cancers (15, 16, 39–42). Cells cultured in serum-free media were pretreated with these inhibitors before stimulation by IGFI. PTEN loss was associated with increased IC50 to the IGFI inhibitors as measured by AKT activation (Fig. 4A). This differential sensitivity was detectable by phosphorylation at both S473 and T308. Interestingly, intermediate sensitivity to these inhibitors was
observed for EWS894 and SK-ES, both of which demonstrated lower PTEN levels and detectable pAKT-S473.

We then examined the effect of PTEN expression on IGF1R inhibition focusing on NVP-AEW541 due to its selectivity for IGF1R (38). Transduced PTEN resulted in enhanced sensitivity for NVP-AEW541 with an IC50 approximating the other PTEN-expressing Ewing sarcoma cells (Fig. 4B). The enhanced sensitivity for NVP-AEW541 was associated with increased cellular toxicity (Fig. 4C). These data suggest that PTEN loss in Ewing sarcoma diminishes the efficacy of IGF1R inhibitors on PI3K signaling as well as viability.

PTEN loss enhances response to temsirolimus

AKT signaling acts on the mTOR pathway to influence multiple cellular processes, including autophagy (43, 44). In light of the emerging role of mTOR inhibition in Ewing sarcoma treatment, we examined the relationship between PTEN loss and autophagic response to the mTOR inhibitor, temsirolimus. Ewing sarcoma cells were treated with

Figure 3. PTEN loss enhances AKT signaling promoting transformation. A, immunoblot for total and phospho-AKT. Ewing cell lines and HUVEC under normal growth conditions were immunoblotted for phospho-AKT at S473 and T308. B, PTEN expression abrogates phospho-AKT. EWS502 were transduced with increasing amounts of PTEN-expressing lentivirus. Extracts were immunoblotted for PTEN, AKT, pAKT S473, pAKT T308, and tubulin. Phospho- and total AKT were quantified. The ratio of pAKT/AKT is shown (bottom). C, PTEN expression reduces cell proliferation. EWS502 were transduced with PTEN on day 0 and cells were counted daily. D, PTEN expression increases apoptosis. Annexin V staining in EWS502 cells transduced with PTEN (black) or a control vector (gray) were analyzed by flow cytometry. Percentages of Annexin-positive cells are shown. E, PTEN expression reduces colony formation. EWS502 transduced with PTEN or control vector were plated in soft agar. Colonies were stained with MTT for visualization (left) and quantified (right). Colonies greater than 1 mm in size were counted. For each panel, error bars represent SE between triplicates. *, P < 0.05; **, P < 0.01, respectively (two-tailed t test).
temsirolimus and autophagy was assayed by quantification of LC3BII, a protein localized to autophagosome membranes that is generated during autophagy (45). The assay was performed in the presence of chloroquine to inhibit lysosomal processing and thus enable assessment of autophagy without ongoing degradation. PTEN-expressing Ewing sarcoma cells (A673) demonstrated minimal LC3BII induction in response to chloroquine or to chloroquine and temsirolimus (Fig. 5A). In contrast, EWS502 cells demonstrated a modest induction of LC3BII in response to chloroquine, but this response was significantly increased by temsirolimus (Fig. 5B). As EWS502, but not A673, cells demonstrated induction of temsirolimus-induced autophagy, we examined the effect of modulating PTEN. Silencing PTEN in A673 cells augmented the autophagic response to temsirolimus, whereas exogenous PTEN expression in EWS502...
eliminated the effect of temsirolimus (but not chloroquine; Fig. 5A and B). We then examined the effect of inhibiting autophagy with chloroquine on cellular viability. Interestingly, treatment with chloroquine attenuated the toxic effects of temsirolimus in the absence of PTEN, but this difference was lost when PTEN was expressed. (Supplementary Fig. S8). Together, these experiments demonstrate that PTEN expression in Ewing sarcoma cells influences autophagic response to temsirolimus with PTEN loss associated with increased responsiveness to mTOR inhibition. Furthermore, the induction of autophagy by temsirolimus is associated with decreased viability, suggesting that autophagy partially mediates the effects of temsirolimus.

**Discussion**

The unexpected identification of PTEN deletion in an Ewing Sarcoma cell line led us to explore the status of PTEN in primary tumors. Although we were unable to detect a similar deletion in other cell lines or a set of primary tumors using FISH, quantitative assessment of PTEN expression by IHC and IF suggested that approximately 25% of Ewing sarcoma tumors are PTEN deficient. Small deletions and other mutations undetectable by FISH, in addition to gene silencing, remain alternative mechanisms that result in PTEN loss in Ewing sarcoma. However, our observation of PTEN loss is consistent with a recent study that used high-resolution SNP arrays to examine copy number variation in Ewing sarcoma and observed PTEN deletion in 14% of the tumors (46).

We found that PTEN deficiency leads to enhanced AKT activation associated with decreased apoptosis, increased proliferation, and anchorage-independent growth. Enhanced properties associated with cellular transformation in Ewing sarcoma could result in a more aggressive tumor phenotype. Intriguingly, ETS deregulation may cooperate with PTEN loss to accelerate tumorigenesis (47). Several lines of evidence indicate that mTOR contributes to PTEN-dependent negative feedback regulation of AKT (reviewed in refs. 48, 49). The loss of PTEN in Ewing sarcoma may be one mechanism mediating hyperactivation of AKT even in the absence of growth factors such as IGF1. In addition to potentially contributing to a more transformed phenotype, hyperactivation of AKT may decrease sensitivity of Ewing sarcoma cells to chemotherapy (50, 51).

We have demonstrated that loss of PTEN decreases sensitivity to IGF1R inhibition, as measured by AKT phosphorylation. Of the limited number of available cell lines tested, there were varying degrees of response to IGF1R inhibition. An intermediate effect was seen in two cell lines with reduced PTEN expression and increased AKT phosphorylation. These findings are consistent with a prior study demonstrating that PTEN silencing in cultured glioblastoma decreased response to NVP-AEW541 (52).

PTEN loss led to increased sensitivity to temsirolimus treatment as marked by the activation of autophagy. Autophagy is a metabolic recycling process in which cellular components are broken down in times of stress to maintain metabolic homeostasis. The role of autophagy in cancer is
complex. Our results suggest that autophagy is required to mediate the cell viability effects of mTOR inhibition by temsirolimus. These data are in agreement with studies indicating that induction of excessive autophagy can lead to cell death (53, 54). mTOR inhibitors may constitute a promising therapeutic class for cancers lacking functional PTEN by inducing autophagy-mediated apoptosis.

PTEN deficiency renders cells less sensitive to IGF1R inhibition but increases autophagic response to mTOR inhibition. The differential response to AKT/mTOR pathway manipulation has therapeutic implications. The promise of personalized therapy for cancer depends on the identification of genetic alterations in specific tumors. The limited efficacy of IGF1R inhibition offers an opportunity for the application of relevant biomarkers. Our results indicate that loss of PTEN expression may diminish the therapeutic response of Ewing sarcoma to IGF1R inhibitors. However, our study also suggests a reciprocal interaction between PI3K/AKT signaling and autophagy. While PTEN loss decreased sensitivity to IGF1R inhibition, it enhanced sensitivity to temsirolimus. These data suggest that patients who are unresponsive to IGF1R inhibition may benefit from mTOR inactivation. The application of PTEN expression as a biomarker to future clinical trial would be needed to directly assess this possibility. Because of the interactions between the IGF1R and mTOR pathways, combination of IGF1R- and mTOR-directed therapies are being evaluated in preclinical and early-phase clinical trials with evidence of efficacy. (55–58). The ability to identify and apply relevant prognostic biomarkers during the selection of biologically active therapies may greatly increase the possibility of therapeutic benefit.
